(REceived 00 Month 200x; in final form 00 Month 200x)

Computer calculations for most exact expected values in blackjack have been available since the 1960's, but the exact results for pair splitting and resplitting have previously been too computer intensive. This paper describes a new algorithm for exact pair-splitting. By using dealer probability caching methods and revising the method for recursively generating possible player hands, the estimated calculation time compared to standard methods was reduced by five orders of magnitude. The resulting algorithm was used to calculate the first exact and complete pair splitting results for the single deck game. The exact results were compared to prior approximate theories for resplitting. The prior theories are accurate for many calculations, but inaccurate for resplitting tens. A new approximation method was developed that is accurate for all resplitting calculations.

Keywords: blackjack; pair splitting; recursive algorithms

AMS Subject Classification: 91A60; 91-04; 68U99

1. Introduction

Many books and articles have been written about the calculation of expected values in blackjack by computer methods. The first accurate derivation of correct strategy was done by Baldwin et al. [1]. Due to limited computer capabilities at that time, they used several approximations. In the 1960's, it was realized the problem was sufficiently small that all hands could be generated and therefore exact expected values could be calculated. Tables of results are given in Thorrp [2] and Epstein [3].

Most blackjack calculations can be completed in seconds. The one exception is for pair splitting. When the player’s first two cards match, the player is permitted to split the cards and play two separate hands. If another matching card is dealt to one of the separate hands, some casinos permit resplitting to make a third or fourth, or potentially even more hands in multideck games. If there are \( n \) possible player hands, computer generation of up to \( h \) split hands requires on the order of \( n^h \) hands. This calculation is feasible for \( h = 2 \) and \( h = 3 \), becomes difficult or impossible for \( h = 4 \) or higher.

There are few published results of pair splitting expected values and none of them are exact. This paper considers the computer problem for finding the exact expected values for pair splitting in a single-deck game for \( h = 2, 3 \), and 4. Initial calculations using conventional blackjack computational methods led to an estimate that calculations for \( h = 4 \) would require about \( 3.4 \times 10^{11} \) seconds or 11,000 years of CPU time. By using memory caching and revising the approach to enumeration of split hands, the total calculation time was reduced by five orders of magnitude.
to $3.9 \times 10^6$ seconds. The new algorithm was used to calculate a table of exact expected values for all rules options. The exact results were compared to the leading approximate approach developed by Griffin [4], and to other tables of splitting results. Griffin’s methods are extremely accurate when resplitting is not allowed, but have some deficiencies when resplitting is allowed. A new approximate method was developed that corrects those deficiencies and agrees with nearly all exact results with absolute errors less than $\pm 0.001$. All other published splitting results deviate more from the exact results.

2. Exact Splitting Algorithm

2.1. Blackjack and Splitting Rules

The rules of casino blackjack will be described briefly with emphasis on defining terms and on the various options for pair splitting. The reader is referred to many references for more details (e.g., [2, 5]). A hand starts by the player making a wager — his initial bet size. The cards are then dealt from a single deck or from multiple decks. The player and dealer each receive two cards and one of the dealer’s cards is exposed and therefore known by the player (the dealer “up card”). Cards 2 through 9 are valued with their number; 10’s and all face cards are valued 10; aces may be valued 1 or 11 at the player’s option. A hand’s score is a sum of values of its cards. A hand with no aces is a “hard” hand. A hand with an ace that does not exceed 21 when the ace is counted as 11 is a “soft” hand (e.g., and hand of A,8 is a soft 19). If all aces in the hand must be counted as 1 to avoid exceeding 21, it becomes a hard hand (e.g., a hand of 8,7,A is a hard 16).

If the dealer’s up card is an ace or a ten card, he checks his second card (the “hole card”) to see if he has a “natural” or blackjack defined as an ace and a ten card adding to 21. If the dealer has a natural, the hand is over the player loses his initial bet, unless the player also has a natural, in which case the hand is a draw or “push” with no loss or gain to the player. If the dealer does not have a natural, the play continues. If the player has a natural, he wins 1.5 times the initial bet regardless of the dealer’s final hand. If the player does not have a natural, his options are to “stand,” “hit,” or “double down” with the objective being to get as close as possible to 21 without going over. If the player stands, his options are over. If the player chooses to hit, he can continue to hit as long as his total is less than or equal to 21. If his total exceeds 21, the hand is a “bust” and the initial bet is lost regardless of the dealer’s final hand. If the player chooses to double down, he increases his bet by an amount equal to the initial bet size and then receives one and only one additional card. Some casinos allow the player to double down on any two cards; other casinos restrict doubling down to only hands of hard 10 or 11.

If the player finishes without busting, the dealer plays his hand by fixed rules regardless of the player’s hand. The dealer exposes his second card and then takes additional cards until the score is 17 or greater. In some casinos, the dealer will hit a soft 17 but stand on all other hands 17 or greater. Once the dealer is done, his score is compared to the player’s. The player wins the current bet size if the dealer busts or if the player’s score is higher that the dealer’s. The player loses if his score is lower than the dealer’s. If the scores are equal, the hand is a push.

This paper is about an additional player option known as pair splitting. If the first two cards are matched (e.g., a hand of 8,8, a hand of 4,4, or a hand of 10,Q; the last example indicates that any two ten cards can be split), the player has the option of splitting the hand. When splitting, the two cards are separated into two
Splitting Pairs in Blackjack

3

hands and a second bet equal to the initial bet size in placed on the second hand. These hands get a second card and play continues as for non-split hands with the following exceptions. If first two cards of a split hand total 21, the hand is not a natural, but just a hand totaling 21. When splitting aces, the player receives one additional card on each hand, but cannot continue with other options. At the two-card stage, the rules between casinos vary. Some casinos do not allow doubling down on such hands. Other casinos allow doubling down on any two-card hand or perhaps only on hands or hard 10 or 11. The rules also vary if the second card matches the original split card. Some casinos allow resplitting, while others do not. For those that allow resplitting, the option is often limited to a maximum of 4 hands or occasionally is allowed for any number of hands (splitting to more than four hands is possible when splitting ten cards or in multideck games). Normally aces cannot be re-split even in casinos that allow resplitting. In rare cases aces can be re-split and the additional hands again receive just one card.

A complete analysis of pair splitting thus requires analysis of all double down options:

(1) No double down after splitting (ND)
(2) Double down on any two cards after splitting (DD1)
(3) Double down only on hard 10 or 11 after splitting (DD2)

To analyze resplitting options as well, the splitting process is allowed to proceed to a maximum of $h$ hands. Setting $h = 2$ gives results when resplitting is not allowed. When $h > 2$, resplitting is allowed. Here the goal was to complete calculations for $h = 4$, which corresponds to a common limitation in casinos that allow resplitting. In a single deck game, $h = 4$ is also unlimited splitting except when splitting 10’s.

2.2. Exact Expected Values

The expected value for any strategy decision is defined as the expected win per unit bet for making a decision and then completing the hand by the zero-memory basic strategy. Zero-memory basic strategy is defined as the decision that maximizes the players expected value based on only knowledge of the dealer’s up card and the player’s initial two cards [3]. The zero-memory basic strategy for any number of decks and for dealers that stand or hit soft 17 is given in Griffin [4]; for completeness, the single-desk basic strategy used for these calculations is in Appendix A.

For example, the exact expected value for hitting a player hand, $\vec{h}$, against dealer up card $u$, can be expressed in a recursive equation as:

$$E(\vec{h}, u) = \sum_{i=1}^{10} p(i) \begin{cases} E(\vec{h} + i, u) & \text{if } \vec{h} + i \text{ should be hit} \\ S(\vec{h} + i, u) & \text{if } \vec{h} + i \text{ should stand} \end{cases}$$ (1)

Here $\vec{h} = (c_1, c_2, c_3, \ldots)$ is a player hand of some number of cards, $\vec{h} + i$ is the new hand formed by adding card $i$ to the end of $\vec{h}$, $p(i)$ is the probability that the next card in the deck has value $i$, $S(\vec{h} + i, u)$ is the expected value if the player stands on the new hand, and “should be hit” or “should stand” refers to basic strategy decision based on the new hand $\vec{h} + i$. The standing expected value is given by:

$$S(\vec{h}, u) = \begin{cases} -1 & \text{if } s(\vec{h}) > 21 \\ d(> 21) + \sum_{i=17}^{s(\vec{h})} d(i) - \sum_{i=s(\vec{h})+1}^{21} d(i) & \text{otherwise} \end{cases}$$

where $s(\vec{h})$ is the score for hand $\vec{h}$, $d(i)$, for $i = 17$ to 21 is the probability the final dealer hand totals $i$, and $d(>21)$ is the probability the dealer busts with a score greater than 21. The first option means the player loses one unit if he busts. Otherwise the player wins one unit if the dealer busts or if $s(\vec{h})$ is higher than the dealer’s score, loses one if the dealer’s score is higher (without busting), or ties if the dealer’s and player’s scores are equal.

Since expected values for blackjack play imply the dealer does not have a natural, the player card probabilities, $p(i)$, are conditional on this fact. The conditional $p(i)$ from Griffin [4] are:

$$p(i) = \begin{cases} \frac{n_i}{n_{\text{deck}}} & \text{for } 2 \leq u \leq 9 \\ \frac{n_i}{n_{\text{deck}}} - \frac{n_{11-u}}{n_{\text{deck}} - n_{11-u} - 1} & \text{for } u = 1, 10 \text{ and } i = 11 - u \\ \frac{n_i}{n_{\text{deck}}} - \frac{(n_{\text{deck}} - n_{11-u} - 1)}{n_{\text{deck}} - n_{11-u}} & \text{for } u = 1, 10 \text{ and } i \neq 11 - u \end{cases}$$

Here $n_i$ is the number cards remaining in the deck with value $i$ and $n_{\text{deck}}$ is the total number of cards remaining in the deck.

The dealer probabilities required for $S(\vec{h}, u)$ can be expressed as a vector function

$$\vec{D}(u, \vec{r}) = (d(17), d(18), d(19), d(20), d(21), d(>21))$$

This function depends on the dealer up card and on the set of cards (besides $u$), $\vec{r}$, that have been removed from the deck. The probabilities can be calculated by a simple recursive algorithm [4]. Like player card probabilities, dealer probabilities are always made conditional on the dealer not having a natural.

### 2.3. Recursive Hand Generation for Pair Splitting

Calculation of exact expected values requires consideration of all possible hands and each hand (or set of hands when splitting) requires a new calculation of dealer probabilities, because they depend on the contents of the player’s hands. A common approach is to use recursive subroutines to generate all hands and sum the results for the exact expected values. This section outlines the heart of C++ code that extends this approach to recursive generation of all possible split hands to any maximum number of hands (the complete source code is posted for downloading [6]). The code is based on three objects called Deck, Dealer, and Hand. The Deck object is responsible for tracking cards in the deck and calculating player weights, $p(i)$. The Dealer object is responsible for calculating dealer probabilities, $D(u, \vec{r})$. Each Hand object tracks one player’s hand and is the focal point for recursive generation of hands.

First consider recursive generation of $E(\vec{h}, u)$ in Eq. (1). A simple recursive method in the Hand object is:

```c++
float Hand::hitExval(Deck &deck, Dealer &dealer)
{
    float exval=0., wt;
    for(int i=ACE; i<=TEN; i++)
    {
        if(!deck.removeAndGetWeight(i,&wt,dealer)) continue;
        hit(i);
        if(basicHit(deck,dealer))
            exval += wt*hitExval(deck,dealer);
        else
            exval += wt*standExval(deck,dealer);
        unhit(i,deck);
    }
    return exval;
}
```
The loop is over the ten possible cards. `deck.removeAndGetWeight()` uses the `Deck` object to remove the card from the deck and calculate the $p(i) = wt$; it returns `false` if no such cards remain in the deck. The `hit()` method adds the card to the hand. If the `basicHit()` method says to hit again, the method is called recursively; otherwise the final hand expected value is calculated by `standExval()`. Finally the card is removed from the hand and restored to the deck (by `unhit()`). When the loop is done, the exact expected value is returned (`exval`).

A method similar to the one above is the core of all blackjack programs for exact expected values. A extension of this approach to recursively generate all possible combinations of split hands, including resplitting, is given by the `exactSplitExval()` method in Appendix B. This method is called as follows:

```java
deck.remove(u,s,s);
dealer.setDDAfterSplitOption(option);
hands[0] = new Hand(s);
hands[1] = new Hand(s);
umSplitHands = 2
exval = hands[0]->exactSplitExval(deck,dealer,hands,
                                numSplitHands,maxHands);
```

The first line removes the dealer up card, $u$, and the two split cards, $s$, from the deck using a `Deck` object. The second line sets the desired double-down-after-split option. Finally, two `Hand` objects are created each with a single split card and the calculation is launched in the first hand. `maxHands` determines $h$ with $h = 2$ for no resplitting or $h > 2$ to allow resplitting. The logic of `exactSplitExval()` is very similar to `hitExval()`. The major difference is that the recursion proceeds through two or more `Hand` objects rather than being confined to a single `Hand`.

The first calculations considered splitting all possible pairs ((A,A), (2,2), ... (T,T)) vs. dealer up card 6 and all double down options (ND, DD1, and DD2). The calculations for maximum number of hands $h = 1$, $2$, or $3$, took 0.69 sec, 49 sec, and 8666 sec, respectively (note: the single hand calculation assumes the expected value of splitting $(s,s)$ is twice the expected value for playing a single hand of $(s)$ [4]). All calculations were done using dual 3 GHz Intel Xeon processors (either a Mac or HP Linux cluster node). Recursive generation of $h$ hands should scale roughly as $N^h$ where $N$ is the effective number of possible single hands. The effective $N$ is seen to be 73 to 176. Repeating that calculations for dealer up card 9 for $h = 1$ or $2$, took 2.75 sec and 4482 secs, for an effective $N = 1631$. Calculations for $h = 3$ were too slow to attempt.

The calculations for dealer up card 6 (and other low cards 2-6) have lower $N$ and complete faster. The calculations for dealer up card 9 (and other high up cards 7-10, A) have a much higher $N$ and take much more time. The reason for lower $N$ vs. low up cards is that basic strategy stops hitting at a low score (12 or 13). Against high up cards basic strategy says to continue hitting to 17 and thus there are many more hands to consider. By considering all up cards and extrapolating observed scaling effects, it was estimated that completing all splitting calculations up to $h = 4$ would take $3.4 \times 10^{11}$ seconds or 11,000 years of CPU time. The remainder of this paper gives strategies for faster calculations.
2.4. Dealer Caching Method

The last step for each generated hand is to calculate its expected value. This step requires generation of all possible dealer hands for the current deck composition to find \( \vec{D}(u, \vec{r}) \). In the process of generating hands, however, the same deck composition will occur many times. Significant improvement in performance is possible by caching dealer probabilities such that the next time the same composition occurs, \( \vec{D}(u, \vec{r}) \) need not be recalculated. The key task is an addressing mechanism for storing dealer results.

Imagine a table to hold all dealer results for decks with 0 to \( j \) cards removed. Because order of removal does not matter, the removed cards are first put into decreasing sequence \( (x_1, x_2, \ldots, x_j) \) with \( x_1 \geq x_2 \geq x_3 \geq \ldots x_j \) and \( x_i = 0 \) to 10 for the type of card removed. A value of \( x_i = 0 \) is used to signify no card removed to handle compositions with less than \( j \) cards removed. Define \( K_j(x_1, x_2, \ldots, x_j) \) as the address found by enumerating through all compositions

\[
K_j(x_1, x_2, \ldots, x_j) = \sum_{i_1=0}^{x_1} \sum_{i_2=0}^{i_1} \cdots \sum_{i_j=0}^{i_{j-1}} 1
\]

until \( i_1 = x_1, i_2 = x_2, \ldots, i_j = x_j \). This address is better defined using a recurrence relation:

\[
K_1(x_1) = 1 + x_1 \quad \text{and} \quad K_j(x_1, x_2, \ldots, x_j) = K_{j-1}(x_2, \ldots, x_j) + \sum_{i=0}^{x_j-1} T_{j-1}(i + 1) \quad (3)
\]

where

\[
T_j(N) = K_j(N-1, N-1, \ldots, N-1)
\]

is the address of the last element in a table required to save \( j \) items in which each item can assume \( N \) states (0 to \( N-1 \)) and is thus the length of that table. Evaluation of \( K_j(N-1, N-1, \ldots, N-1) \) using Eq. (3) gives

\[
T_j(N) = \sum_{i=0}^{N-1} T_{j-1}(i + 1)
\]

which leads to

\[
K_j(x_1, x_2, \ldots, x_j) = 1 + \sum_{i=1}^{j} T_i(x_{j-i+1}) \quad (4)
\]

From the definition of \( T_j(N) \) initiated with \( T_1(N) = N \):

\[
T_2(N) = \frac{N(N+1)}{2}, \quad T_3(N) = \frac{N(N+1)(N+2)}{2 \cdot 3}, \quad T_j(N) = \binom{N+j-1}{j} \quad (5)
\]

A dealer cache is created by setting \( j \) to maximum allowed by available memory. Each time the dealer probabilities are needed, the address is calculated by Eq. (4). To avoid repeated evaluation of \( T_j(N) \), all needed values can be pre-calculated and stored in a \( j \times 11 \) array. The first time an address is encountered, the dealer probabilities are calculated and stored in the cache. All subsequent times, the
probabilities are retrieved and used. The length of the dealer cache is $T_j(11)$. If the values are stored as floats, each entry requires 24 bytes. The largest cache used was $j = 23$ requiring 2.23 GB of storage.

Figure 1 shows the effect of dealer cache size on calculation of all splitting options (ND, DD1, and DD2) for all pairs against dealer up cards of 6 or 9 and various values of $h$. Very small caches are no help, but once the cache size reaches the common hand size, the speed drops rapidly showing improvements of up to two orders of magnitude. Larger cache sizes are required as $h$ increases. The time may increase again at very large cache size (e.g., 1 hand results in Fig. 1) if the time needed to allocate and initialize the cache is non-negligible compared to the calculation time.

The next calculations were to consider all possible splitting options (ND, DD1, and DD2) for all possible dealer up cards using optimum cache sizes. The average calculation times for low (vs. 2-6, Recursive) or high (vs. 7-T and A, Recursive) dealer up cards are plotted as a function of the number of hands, $h$, in Fig. 2. The scaling was approximately $N^h$, with $N$ effectively $N = 50$ to 100 for low up cards and over 2200 for higher up cards.. Calculations up to 4 hands with low dealer up cards were completed, but calculations for high dealer up cards were still too slow. The dashed line in Fig. 2 extrapolates the time to $h = 4$ for high dealer up cards by mimicking the increase in effective $N$ for low up cards. The extrapolation led to an estimate of $5.0 \times 10^9$ or 160 years of CPU time for all calculations — a significant improvement, but still too long.

2.5. Pre-enumerated Hands Method

The problem with recursive hand generation is that it is inefficient. The method revisits many hands of identical composition, but differing only by the order in which the hand receives the cards. For example, when splitting 2’s vs. dealer 9, recursive methods generate 21,166 hands, but only 1527 of those hands are unique. The next improvement was to first catalog all unique hands and then evaluate splitting expected values by enumerating over only the unique hands.

The cataloging of unique hands was done by recursive generation of all possible single hands. An array of PlayHand objects was constructed to hold the hands. For each unique hand, the PlayHand object tracks the card composition of the hand, the

Figure 1. The effect of dealer cache size on splitting calculation times for dealer up card 6 (solid lines) or 9 (dashed lines) with total play allowed to 1 hand, 2 hands, or 3 hands.
number of times the hand occurs, the number of times the second card in the hand is another split card, the total bet size on all hands, and total bet size on potential split hands. Tracking the second card is needed to allow resplitting calculations. Tracking the bet size is needed to support doubling down after splitting options. The dealer cache addressing methods were used to efficiently determine whether each generated hand is a new hand or corresponds to a previously generated hand. A hand look-up table of $T_j(11)$ integers, where $j$ is the maximum hand length, was created and filled with -1. Each hand uses Eq. (4) to find an address from its decreasing card composition. If the table entry at that address is -1, a new PlayHand object is created and added to the end of the array of unique hands. The location of the new hand in that array is then stored in the hand look up table. The next time the same hand occurs the look up table will provide the location of that hand in the array of unique hands and the new information can be appended to the existing PlayHand object. Notice that building a list of unique hands requires recursive generation of hands. For calculations of exact expected values of single hands, there is no benefit to this approach and thus no benefit to any other blackjack calculations. For exact splitting calculations, however, the list of unique hands greatly reduces the effective $N$ for algorithm scaling and thus makes the calculations possible.

Once the unique hands are collected, the exact splitting expected values are evaluated as above except using the new handExactSplitExval() method in Appendix C:

```c
exval = hands[0]->handExactSplitExval(deck,dealer,hands,
numSplitHands,maxHands,handList);
```

The last argument is an array of PlayHand objects for all possible unique hands for the current splitting rules. The average calculation times for low (vs. 2-6, Hands) or high (vs. 7-T and A, Hands) dealer up cards are plotted as a function of the number of hands, $h$, in Fig. 2. For low up cards, the calculation times decreased by

---

1The maximum hand length in a split hand played by basic strategy with infinite decks is 14 cards. The hand is (1,1,1,1,1,1,1,4,1,1,1,1,1) corresponding to split aces played out as normal hands. The 4 as the ninth card is when hitting soft 18 converts the hand to a hard 12.
an order of magnitude for \( h > 2 \) and the effective \( N \) was reduced to 12 to 50. For high up cards the times for \( h = 4 \) decreased about three orders of magnitude. The effective \( N \) was reduced to 250 and did not increase with \( h \). Figure 2 also shows the total calculation time to find expected values for all dealer up cards, all splitting pairs, and all splitting options (ND, DD1, and DD2) for a single deck game. The calculations for \( h = 4 \) took \( 3.9 \times 10^6 \) sec or 45 days — five orders of magnitude faster than non-optimized recursive methods. The calculations were done using idle time on a 32-processor cluster by partitioning into different up cards and different splitting pairs. Some calculations took much longer than others. 71.6% of the calculation time was needed for up cards 7, 8, and 9; 43.4% of the time was for splitting of just (2,2) and (3,3) for up cards 7, 8, and 9.

### 3. Results and Discussion

Tables 1 and 2 give exact splitting expected values for all split pairs against all dealer up cards in a single-deck game where the dealer stands on soft 17. Each table cell has four numbers. The first row is when resplitting is not allowed; the second row is when resplitting is allowed (to a maximum of 4 hands). Within each row, the first value is when doubling down after splitting is not allowed; the second value is when doubling down after splitting on any two cards is allowed. Splitting of aces assumes each hand gets a single card. Resplitting of aces means if the single card is another ace, the pair can be split again, but still only receives a single card. Exact calculations were also completed for dealer hitting soft 17 and for double down after splitting on only 10 and 11. Those results are not included in table, but are included in the total CPU times. Thus the total CPU time is the time required to analyze all possible splitting rule variations in a single deck game.

Prior to these exact calculations, the best splitting calculations used the approximate methods developed by Griffin [4]. If \( \vec{h}_i \) for \( i = 1 \) to \( n_h \) is the collection off all possible unique hands for one splitting situation, the exact expected value for splitting a pair of \( s \) cards when resplitting is not allowed can be written explicitly as

\[
E_s(\vec{h}(s, s), u) = \sum_{i=1}^{n_h} \sum_{j=1}^{n_h} w(\vec{h}_i)w(\vec{h}_j|\vec{h}_i) \left[ b(\vec{h}_i)S(\vec{h}_i, u, \vec{h}_j) + b(\vec{h}_j)S(\vec{h}_j, u, \vec{h}_i) \right]
\]

Here \( w(\vec{h}_i) \) is the weight for hand \( i \) defined as the probability of hand \( i \) times the number of times that unique hand occurs, \( w(\vec{h}_j|\vec{h}_i) \) is the analogous weight for hand \( j \) given that hand \( i \) has been removed from the deck, \( b(\vec{h}) \) is the average bet size for a hand, and \( S(\vec{h}_i, u, \vec{h}_j) \) is the expected value for standing on hand \( i \) against dealer up card \( u \) given that both hand \( i \) and \( j \) have been removed from the deck. Note that \( b(\vec{h}) = 1 \) when doubling down after splitting is not allowed, but \( b(\vec{h}) > 1 \) when it is allowed and one or more occurrences of the hand should be doubled. Griffin’s approximate result [4] can be expressed as

\[
E_s(\vec{h}(s, s), u) \approx 2E(\vec{h}(s), u, s) = 2 \sum_{i=1}^{n_h} w(\vec{h}_i)b(\vec{h}_i)S(\vec{h}_i, u, s)
\]

where \( E(\vec{h}(s), u, s) \) is the expected value of playing out a hand with a single card \( s \) against a dealer up card given that the second \( s \) card has also been removed from the deck. The exact and approximate methods agree within \( \pm 0.000003 \) for all splitting
Table 1. Exact splitting expected values vs. dealer up cards Ace through 5 for a single deck game where dealer stands on soft 17. The first row of each cell is when resplitting is not allowed; the second row is when resplitting is allowed to 4 hands. The first column of each cell is when doubling down after splitting is not allowed; the second column is when it is allowed on any two cards. A decimal point in front of each number has been omitted to save space.

</table>
calculations. Hawkins [7] compared one exact non-resplitting calculation to Griffin’s approximate formula and concluded the similarity implies the approximate formula is exact. Comparison of Eq. (6) to Eq. (7), however, shows they are only identical if

\[ S(\vec{h}_i, u, s) = \frac{1}{2} \sum_{j=1}^{n_h} w(\vec{h}_j|\vec{h}_i) \left[ S(\vec{h}_i, u, \vec{h}_j) + \frac{b(\vec{h}_j)}{b(\vec{h}_i)} S(\vec{h}_j, u, \vec{h}_i) \right] \]

Since averaging over all hands \( \vec{h}_j \) is expected to average out variations in \( S(\vec{h}_i, u, \vec{h}_j) \), the equation is likely to be accurate. Calculations show it is extremely accurate, but it is not possible to prove the approximate approach is exact.

Calculations when resplitting is allowed are much more complicated. The state-of-the-art, prior to these exact results, is again due to Griffin [4]. The approximate equation is

\[ E_s(s, s, u) \approx \sum_{i=2}^{h} iP(i)E(i) \]

where \( P(i) \) is the probability of playing exactly \( i \) hands, \( h \) is the maximum number of hands, and \( E(i) \) is a single hand expected value calculated as follows:

1. Calculate the expected value for a single hand starting with an \( s \) card for a deck with the dealer up card and \( i \) of the \( s \) cards removed from the deck.
2. The player hand cannot draw an \( s \) card as the second card in the hand.
3. The dealer expected values are found conditional that the \( i-1 \) additional player hole cards are not \( s \) cards.

The third requirement means dealer expected values calculated for this analysis differ from all other calculations and thus results stored in the dealer cache cannot be used. The probability of card \( k \) for dealer play when finding \( E(i) \) for splitting \( s \) cards is

\[ p(k, i, s) = \begin{cases} \frac{n_k}{n_{\text{deck}} - i + 1} & \text{for } k = s \\ \frac{n_k}{n_{\text{deck}} - i + 1} \left( \frac{n_{\text{deck}} - n_s - i + 1}{n_{\text{deck}} - n_s} \right) & \text{for } k \neq s \end{cases} \]

For calculations to a maximum of four hands \((h = 4)\), \( E(4) \) can allow the hand to draw an \( s \) for its second card, the dealer expected values are unaffected by player hole cards, and \( P(4) \) is set to \( P(4) = 1 - P(2) - P(3) \).

The approximate analysis was compared to the exact results. For splitting of aces, and 2 through 9, the approximate equation is very accurate, but not as accurate as the approximate non-resplitting equation. Nearly all results agree with ±0.0010. The few exceptions are splitting 4’s vs. 5 and 6 and splitting 5’s vs. 4 and 6. The largest error was ±0.0016. The result for splitting 10’s were not as good. The errors ranged up to ±0.1000. The problem is that \( P(4) \) is much larger and the calculation of \( E(4) \) is less accurate.

A new approximate analysis was developed that significantly improves on Griffin’s approach when splitting 10’s and further improves the accuracy for all other calculations. When \( h = 4 \), it takes 4 cards to resolve the total hand play. Let \( s \) be a split card and \( n \) be a non-split card. The 16 possible orders for \( n \) and \( s \) cards in 4 cards are classified as in Table 3.
Table 3. All possible sequences of four cards of type n (for non-split card) and s (for split card) and the approximate expected value and probability appropriate for that sequence.

</tr>
</tbody>
</table>

Actually two hands will be played. The approximate expected value is 2E(2) and the probability of those four sequences in P(2). The remaining lines partition 3- and 4-hand situations to refine the approximate calculation. For example, the second row has order nsnn. The first n means the first hand is played out when only two s cards have been removed from the deck and thus has approximate expected value E(2). The next s means the second hand is split; the following two n’s mean those hands are played resulting in three final hands. Since the last two hands are played with three s card removed, their approximate expected values are E(3) each. The expected value of the second row is E(2) + 2E(3). The probability is denoted as P(3/1). Similar logic applies to all remaining rows. Finally, the revised approximate expected value for splitting when resplitting is allowed is

\[
E_A(h(s, s), u) \approx \left[ 2P(2) + P(3/1) + P(4/1) + P(4/2) \right] E(2) \\
+ \left[ 3P(3) - P(3/1) + P(4/1) + 2P(4/3) + P(4/4) \right] E(3) \\
+ \left[ 4P(4) - 2P(4/1) - P(4/2) - 2P(4/3) - P(4/4) \right] E(4)
\]

Notice that this new approximation still depends only on E(2), E(3), and E(4) and thus is no more work than Griffin’s method. It simply revises the probabilities associated with each expected value. These probabilities can be easily calculated by methods in Griffin (see Appendix D) and it is noted that P(3) = P(3/1) + P(3/2), and P(4) = P(4/1) + P(4/2) + P(4/3) + P(4/4) + P(4/5). The revised approximate analysis improves agreement for splitting 10’s with the exact results by more than an order of magnitude. The largest errors are reduced from ±0.100 to ±0.006 with many errors under ±0.004.

Although many books and articles give splitting strategy, very few references provide splitting expected values. Perhaps the first are tables in Thorp’s *Beat the Dealer* [2]. His tables give expected values (to three significant digits) for all pairs against all up cards for a single deck game where resplitting is not allowed, doubling down after splitting is allowed on any two cards, and the dealer stands on soft 17. Epstein [3] gives essentially the same expected values (but to four significant figures). Although Epstein claims to have analyzed resplitting allowed, his tables are much closer to results when resplitting is not allowed then when it is allowed. The mean errors in these tables compared to the exact results are ±0.022 with some errors ±0.07. Neither reference gives sufficient information to explain the discrepancy. Epstein states an approximate formula analogous to Eq. (7), but since that equation is accurate, he must have used it incorrectly. As noted by Griffin [4], the single hand expected value for splitting calculations should be found with the
second card removed from the deck. To check if Thorp and Epstein omitted this refinement (since there work was prior to Griffin [4]), new calculations were run without removing the second card. These new results cut the Thorp and Epstein mean error in half to ±0.011 and maximum error to ±0.027. In summary, these historic table are not particularly accurate, probably used the wrong approximate formula, and only provide results for one set of splitting rules.

Manson et al. [8], did calculations for a four deck game with resplitting allowed, doubling down allowed on any two cards, and dealer stands on soft 17. They estimated that exact calculations would take 100 times longer than their other calculations (an estimate that is off by about 9 orders of magnitude), and therefore did all splitting calculations by Monte Carlo simulations. Their table only gives splitting expected values for hands in which splitting is the most favorable option. Because exact results for multiple decks have not be done yet, these results were compared instead to the new approximate analysis for resplitting in four decks to four hands. The mean absolute error of all their available calculations is ±0.019; the maximum error is ±0.04. These errors are similar to independent Monte Carlo simulations run during this work and probably representative of expected errors for the simulation approach.

Hawkins [7] gives results for a six deck game with no doubling down after splitting and dealer hits soft 17. The analysis used the Griffin [4] approximate methods and gives expected values for either resplitting allowed or resplitting not allowed, depending on which was more favorable. When the table gives non-resplitting results, the results are usually identical to new calculations also using Eq. (7). The two exceptions are vs. dealer up cards of ace and ten and for splitting (3,3) vs. dealer up card 8. The problems with dealer up card ace and ten suggest Hawkins did not follow Griffin methods to account for the effect on player card probabilities of the knowledge that the dealer does not have blackjack [4]. Hawkins results for splitting (3,3) vs. 8 were off by exactly a factor of 2 suggesting it was a misprint (i.e., omitted the 2 in Eq. (7)). Hawkins resplitting results were compared to the new approximate analysis for resplitting; they agree well with a mean absolute error of ±0.0005. The main limitation of Griffin’s methods, which was corrected by the new approximation, was when resplitting 10’s. Since the Hawk’s table did not give any results for resplitting 10’s, new calculations were run by both methods. The Griffin method and the new method differ with a mean error of ±0.07; the new approximation is claimed to be more accurate.

As indicated in Hawk’s table [7], and in these new results, if splitting once is favorable, then resplitting is more favorable. Conversely, if the first split is unfavorable, resplitting is more unfavorable. For example, the expected values for splitting of tens to a maximum of one hand (i.e., standing on the twenty), two hands, three hands, or four hands, vs. dealer up card of 6 are 0.697403, 0.525105, 0.426506, and 0.363571. In basic strategy, it is never favorable to split tens and thus the decreasing expected values are not relevant. In card-counting strategies, however, one can calculate a cutoff count for splitting tens [4]. When the count exceeds the cutoff value, splitting of tens becomes favorable. But, the cutoff values to continue splitting to more hands will be much higher than the cutoff for the first split. Furthermore, because additional tens that allow resplitting will lower the count, it is highly unlikely for the count to ever be high enough to split tens more than once or twice. A common story in card-counting books is about using the count to split and resplit tens [9, 10]. In these stories, the first split may have been correct, but it is likely each resplit is giving advantage back to the house. The stories are meant to convey card-counting prowess, but rather show a lack of awareness about the expected values for resplitting. Indeed, an extreme example in
Table 4. Effect of various splitting rules on the total expected value for the game of blackjack (listed in %). The two sections are for doubling down on any two hands or doubling down on just 10 & 11. The numbers in parentheses are the changes in expected value from the baseline in each section. The baseline is for no resplitting and no doubling down after splitting. The “Resplit” rows are for resplitting all pairs except aces or resplitting all pairs including aces.

</tbody>
</table>

Uston [9] describes a pair of tens split to 11 hands resulting in a loss of $5000. The result was attributed to bad luck despite “correct plays.” More likely, the correct play was to split only once or twice.

Finally, by combining exact splitting results with easily-calculated exact results for standing, hitting and doubling down, it is possible to get the exact expected value for blackjack including the influence of all possible splitting rules variations. The results are summarized in Table 4. The left half is for games that allow doubling down on any two cards with the upper-left cell for no resplitting and no doubling down after splitting as a base line. The other cells give the expected value for altering the splitting rules. The numbers in parentheses are the increments over the base line. The same calculations for games that restrict doubling down to 10 and 11 are in the right half of the table. The last row is when splitting is prohibited. The net benefit to the player of allowing splitting is between +0.357% and +0.546% (depending on splitting options allowed). This benefit is small because the total number hands worth splitting is small. Although 11.8% hands could be split, most of them are hands that should not be split (e.g., (10,10)). Under favorable rules, only 2.5% of hands provide beneficial splitting opportunities.

4. Conclusions

The problem of splitting in a one deck game when resplitting is not allowed or when resplitting is allowed to a maximum of four hands were both solved by computer methods. The exact calculations when resplitting is not allowed can be done reasonably fast. The results showed that prior approximate calculations when resplitting is not allowed are extremely accurate. The exact calculations when resplitting is allowed are time consuming, but the methods here make them possible given sufficient computer power. The new exact results showed that approximate methods were inaccurate for splitting 10’s. A new approximate solution was developed. It can be done rapidly and is accurate to ±0.001 for all splitting calculations except for splitting 10’s, and accurate to ±0.006 for splitting 10’s.

The overall effect of splitting in blackjack is relatively minor. These calculations do not significantly alter previously calculated expected values and do not recommend any changes in previously published strategies for splitting. Solving the splitting problem, however, was an interesting computer challenge. It provides an example of how the simpler coding, here represented by the recursive approach, may be inefficient. When recursion is too repetitive, significant improvements can be made by revising the enumeration methods.

Although the exact calculations for splitting are lengthy, if all rule variations are included, they only need to be done once. A complete table requires twelve
calculations for each split pair vs. each dealer up card. There are six calculations comprised of the three double down options (ND, DD1, and DD2) when the dealer hits soft 17 and the same three options when the dealer stands on soft 17. These six calculations have to be repeated for resplitting not allowed and for resplitting allowed. The tables in this paper only include four of these twelve results for the one-deck game. They include results are for ND and DD, for resplitting allowed or not allowed, and only for dealer stands on soft 17. The remaining exact calculations for the one-deck game are posted on the source-code web site [6]. The exact calculations for multideck games have not been done and would require somewhat more computer time. Multideck results for all twelve calculations, however, were run using the new approximate methods; these results are also posted on the source-code web site [6].

Appendix A. Basic Strategy

The single-deck basic strategy for hitting and doubling down used in these calculations was

(1) Hard Hitting: Hit 12 or less vs. dealer up card 2 or 3 (except hit (10,3) vs. 2 if dealer stands on soft 17 and stand on (8,4), (7,5), and (6,6) vs. 3), hit 11 or less vs. 4 to 6 (except hit (10,2) vs. 4 and hit (10,2) vs. 6 if dealer stands on soft 17), and hit 16 or less vs. 7 to 10 or Ace (except stand on (7,7) vs. 10 and stand on 16 with 3 or more cards vs. 10).

(2) Soft Hitting: Hit soft 17 or less vs. dealer up card 2 or 8, hit soft 18 or less vs. 9, 10 and Ace (except stand soft 18 vs. Ace if dealer stands on soft 17).

(3) Hard Doubling Down: Double 9 to 11 vs. dealer up card 2 to 4, double 8 to 11 vs. 5 and 6 (except hit (6,2) vs. 5 if dealer stands on soft 17 and hit (6,2) vs. 6), double 10 and 11 vs. 7 to 9, and double 11 vs. 10 and Ace.

(4) Soft Doubling Down: Double (A,6) vs. 2, double (A,6) and (A,7) vs. 3, double (A,2) to (A,7) vs. 4 and 5, and double (A,2) to (A,8) vs. 6.

The basic strategy for splitting is not needed in the calculations but can be determined from the results.

Appendix B. Recursive Hand Generation

Exact expected values by recursive generation of all possible split hands is accomplished by the following method:

```c
float Hand::exactSplitExval(Deck &deck, Dealer &dealer, Hand **hands, int &numSplitHands, int maxSplitHands)
{
    float exval = 0., wt, totalVal;
    bool newHand = false;

    for(int i=TEN; i>=ACE; i--)
    {
        if(!deck.removeAndGetWeight(i,&wt,dealer)) continue;

        // add new hand or new card
        if(i == firstCard && &cards == 1 && numSplitHands < maxSplitHands)
        {
            hands[numSplitHands++] = new Hand(firstCard);
            newHand = true;
        }
        else
            hit(i);
    }
```
Splitting Pairs in Blackjack

// hit again, continue to next hand, or add to probabilities
if(basicSplitHit(deck, dealer))
    exval += wt*exactSplitExval(deck, dealer, hands,
                   numSplitHands, maxSplitHands);
else if(this != hands[numSplitHands-1])
    exval += wt*nextHand->exactSplitExval(deck, dealer, hands,
                   numSplitHands, maxSplitHands);
else
{   totalVal=0.;
    for(int j=0; j<numSplitHands; j++)
        totalVal += hands[j]->getExpectedWin(deck, dealer);
    exval += wt*totalVal;
}

// delete new hand or unhit and then return card to the deck
if(newHand)
{   delete hands[numSplitHands--];
    newHand=false
}
else
    unhit(i);
    deck.restore(i);
}
return exval;

The loop is over the ten possible cards. deck.removeAndGetWeight() uses the Deck object to remove the card from the deck and calculate the \( p(i) = wt \); it returns false if no such cards remain in the deck. If the current card is another split card (and is the second card in the hand), a new hand is created providing the total number of hands in less than \( h \) (in maxSplitHands), otherwise the hit() method adds the card to the hand. If the basicSplitHit() method says to hit again, the method is called recursively; the basicSplitHit() method also checks if the hand should be doubled. If the hand is not hit and the current hand is not the last hand, the exactSplitExval() method is called in the next hand object; otherwise for the last hand, the results for all hands, accounting for doubled hands, are summed and then added with proper weighting to the expected value. If a new hand was created, it is deleted; otherwise the card is removed from the hand (by unhit()). Finally, the loop card is restored to the deck. When the loop is done, the exact expected value is returned (exval).

Appendix C. Pre-Enumerate Hands Method

Exact expected values using a previously calculated list of all possible hands (in handList) is accomplished by the following method:

float Hand::handExactSplitExval(Deck &deck, Dealer &dealer, Hand **hands,
                   int &numSplitHands, int maxSplitHands, handset &handList)
{
    float exval = 0., wt, totalVal;

    // check for resplitting
    if(numSplitHands<maxSplitHands)
    {   if(deck.removeAndGetWeight(firstCard,&wt,dealer))
        {   hands[numSplitHands] = new Hand(firstCard);
            hands[numSplitHands-1]->setNextHand(hands[numSplitHands++]);
            exval += wt*handExactSplitExval(deck, dealer, hands,
                   numSplitHands, maxSplitHands, handList);
        }
    }
    else
    {   totalVal=0.;
        for(int j=0; j<numSplitHands; j++)
            totalVal += hands[j]->getExpectedWin(deck, dealer);
        exval += wt*totalVal;
    }
    return exval;
}
numSplitHands, maxSplitHands, handList);
delete hands[--numSplitHands];
deck.restore(firstCard);
}
}

// hand loop
for(int i=0; i<handList.size(); i++)
{
    // get non-splitable fraction or entire hand
    if(numSplitHands<maxSplitHands && handList[i]->isSplitable())
    {
        if(!handList[i]->removeAndGetNonsplitWeight(deck, dealer, &wt))
            continue;
        handList[i]->fillNonsplitHand(this);
    }
    else
    {
        if(!handList[i]->removeAndGetWeight(deck, dealer, &wt))
            continue;
        handList[i]->fillHand(this);
    }

    // add to probabilities or continue to next hand
    if(this==hands[numSplitHands-1])
    {
        totalVal = 0.;
        for(int j=0; j<numSplitHands; j++)
            totalVal += hands[j]->getExpectedSplitWin(deck, dealer);
        exval += wt*totalVal;
    }
    else
    {
        exval += wt*nextHand->handExactSplitExval(deck, dealer, hands,
                                          numSplitHands, maxSplitHands, handList);
    }

    // remove all cards from hand and restore to the deck
    handList[i]->removeHand(this, deck);
}
return exval;
}

This method is similar to the recursive exactSplitExval() in Appendix B; the important differences are as follows. The handExactSplitExval() method is called with an array of PlayHand objects in handList; these objects have all possible hands that can be played in the current splitting calculation. Since the list of hands is for playable hands, the method has to begin with a separate check for resplitting opportunities. If it is possible to resplit, a new hand is created, handExactSplitExval() is called recursively, and then the new hand is deleted.

The main loop is over all possible hands rather than over possible cards. The first steps in the loop are to remove all cards in the next playable hand, get the weight for that hand, and populate the current Hand object with those cards. The key to these steps is to account for playable hands that may include one or more hands that could be resplit; i.e., one or more of the hands described by the PlayHand object is a hand where the second card is another split card. When the current number of hands is less the the maximum and the current PlayHand object includes splitable hands, the weighting must be adjusted to include just the non-splitable fraction of the hand; otherwise the entire PlayHand content is used. The removeAndGetNonsplitWeight() or removeAndGetWeight() functions remove all cards in the PlayHand object from the deck and adjust the weight according to the frequency of that hand; the methods return false if the hand is not possible from the current remaining cards. The fillNonsplitHand() and fillHand() methods add the
cards to the current Hand object and also calculate the average bet per hand to adjust for frequency of doubled hands in the current PlayHand object.

Next, if the current hand is the last hand, the total expected win for all hands is summed and added to the total expected value. The getExpectedSplitWin() function adjusts the win rate to average bet size per hand to allow calculations with doubling down after splitting. If the current hand is not the last hand, control is passed to the next player hand. Finally, all cards in the current PlayHand object are removed from the current Hand object and restored to the deck. When the loop is done, the exact expected value is returned (exval).

Appendix D. Probabilities for Approximate Splitting Calculations

Define $p_j(s)$ as the probability that the first split card is drawn in the $j^{th}$ position and $p_j(s|s)$ as the probability that the second split card is drawn in the $j^{th}$ position. They are calculated from player card probabilities in Eq. (2):

$$p_1(s) = p(s)$$
$$p_2(s) = p(s) \text{ given } n_{\text{deck}} \rightarrow n_{\text{deck}} - 1$$
$$p_2(s|s) = p(s) \text{ given } n_s \rightarrow n_s - 1, \ n_{\text{deck}} \rightarrow n_{\text{deck}} - 1$$
$$p_3(s) = p(s) \text{ given } n_{\text{deck}} \rightarrow n_{\text{deck}} - 2$$
$$p_3(s|s) = p(s) \text{ given } n_s \rightarrow n_s - 1, \ n_{\text{deck}} \rightarrow n_{\text{deck}} - 2$$
$$p_4(s) = p(s) \text{ given } n_{\text{deck}} \rightarrow n_{\text{deck}} - 3$$
$$p_4(s|s) = p(s) \text{ given } n_s \rightarrow n_s - 1, \ n_{\text{deck}} \rightarrow n_{\text{deck}} - 3$$

Then the required probabilities for approximate splitting calculations are

$$P(2) = \left[1 - p_1(s)\right] \left[1 - p_2(s)\right]$$
$$P(3/1) = \left[1 - p_1(s)\right] p_2(s) \left[1 - p_3(s|s)\right] \left[1 - p_4(s|s)\right]$$
$$P(3/2) = p_1(s) \left[1 - p_2(s|s)\right] \left[1 - p_3(s|s)\right] \left[1 - p_4(s|s)\right]$$
$$P(4/1) = \left[1 - p_1(s)\right] p_2(s) \left[1 - p_3(s|s)\right] p_4(s|s)$$
$$P(4/2) = \left[1 - p_1(s)\right] p_2(s) p_3(s|s)$$
$$P(4/3) = p_1(s) \left[1 - p_2(s|s)\right] \left[1 - p_3(s|s)\right] p_4(s|s)$$
$$P(4/4) = p_1(s) \left[1 - p_2(s|s)\right] \left[1 - p_3(s|s)\right]$$
$$P(4/5) = p_1(s)p_2(s|s)$$
